# Chapter 1

## Find all zeros of function

### 1.1 a) False position method

#### 1.1.1 Problem

We have to find zeros of the function

$$f(x) = -2.1 + 0.3x - xe^{-x}$$

In the interval  $[-5; 10]$  using false position method.

#### 1.1.2 Theoretical Introduction

*False position* method also called *regula falsi* in fancier circles is similar to the bisection method, the difference is that the interval we use  $[a_n, b_n]$  is divided into two subintervals. We have:

- $\alpha$  - The root
- $a_n$  - 'left' interval
- $b_n$  - 'right' interval
- $f(a_n)$  - Value at left interval
- $f(b_n)$  - Value at right interval

We get:

$$\frac{f(b_n) - f(a_n)}{b_n - a_n} = \frac{f(b_n) - 0}{b_n - c_n}$$

From which we get:

$$c_n = b_n - \frac{f(b_n)(b_n - a_n)}{f(b_n) - f(a_n)} = \frac{a_n f(b_n) - b_n f(a_n)}{f(b_n) - f(a_n)}$$

Then we choose next interval as in the bisection method so: we calculate products of function values at  $a_n$  and  $b_n$  and that subinterval is selected for the next iteration of *false position* method. This subinterval corresponds to the negative product value.

### Properties of *false position method*

This method is always convergent, simillary to bisection method, since it will always choose and shorten the interval which contains the root. If the function is continous and differentiable the method is linearly convergent. That being said the convergence may become sluggish. It can happen if for example one of the endpoints of the intervals will remain the same and the iterating will not shorten the interval to 0. One of the examples of functions that lead to that are barrier functions used in constrained optimization methods.

**Improvement to the method** In order to improve the formula and avoid aforementioned situation we can take smaller value of the function for the value that does not change. For right end:

$$c_n = \frac{a_n \frac{f(b_n)}{2} - b_n f(a_n)}{\frac{f(b_n)}{2} - f(a_n)}$$

And for left end:

$$c_n = \frac{a_n f(b_n) - b_n \frac{f(a_n)}{2}}{f(b_n) - \frac{f(a_n)}{2}}$$

This is called *modified regula falsi* or *Illinois algorithm*. It is superlinearly convergent, globally convergent and length of intervals we get in each iterations converges to zero.

## 1.2 b) the Newton's method

### 1.2.1 Problem

We have to find zeros of the function

$$f(x) = -2.1 + 0.3x - xe^{-x}$$

In the interval  $[-5; 10]$

using the Newton's method

### 1.2.2 Theoretical Introduction

*The Newton's method* also called *the tangent method* relies on first order part of its expansion into Taylor series for a given current approximation of root.

$$f(x) \approx f(x_n) + f'(x_n)(x - x_n)$$

Then we obtain the next point  $x_{n+1}$  by finding root of linear function:

$$f(x_n) + f'(x_n)(x_{n+1} - x_n) = 0$$

From this we get formula for  $x_{n+1}$ :

$$x_{n+1} = x_n - \frac{f(x_n)}{f'(x_n)}$$

This method as opposed to *regula falsi* method is locally convergent, should we choose initial point too far from the root (area which is close enough to root is called set of attraction) then we can get a divergence. On the other side if the Newton's method will converge then it is quite rapid with convergence of order  $p = 2$  - quadratic convergence.

Newton's method is also effective if the function derivative is far from zero, so the slope of the function is steep, conversely if the derivative is close to zero the method is not recommended.

### 1.2.3 Results

Iteration	root	f(root)

3	7.0209	-9.517e-08
4	7.0209	7.468e-16

### 1.2.4 Discussion of results

As we can see and as we could expect from theory Newton method reigns supreme. It is:

1. Faster. Especially for finding first root. It took 36 iterations for false position method to find first root with accuracy up to  $10^{-10}$  and it took only 6 iterations for the Newton method.
2. More accurate Not only that we also got more accurate results with Newton method! With first root being so close to the real answer that

the matlab calculated the value of this function at this point as exactly equal to 0. For second root the accuracy is  $10^6$  better than for the false position method.

3. Smaller gaps Looking at graphs we got from both methods we can clearly see that the gaps between the final result and each and every step are much smaller for Newton method. This again proves that it is faster and more accurate compared to false position method.

## Chapter 2

# Find real and complex roots of the polynomial

### 2.1 Problem

We have to find all real and complex roots of the polynomial:

$$f(x) = a_4x^4 + a_3x^3 + a_2x^2 + a_1x + a_0$$

where:

$$[a_4 \ a_3 \ a_2 \ a_1 \ a_0] = [-2 \ 12 \ 4 \ 1 \ 3]$$

So our polynomial looks like this:

$$f(x) = -2x^4 + 12x^3 + 4x^2 + 1x + 3$$

Using the Müller's method. We have to implement both MM1 and MM2 versions. We also need to find real roots using the Newton's method and compare these results with what we got from MM2 version of the Müller's method.

### 2.2 Theoretical Introduction

Müller's method revolves around the idea of approximating the polynomial locally close to the root by a quadratic function. Based on three different points we can use quadratic interpolation and develop our method. This means that we can treat it as a generalization of secant method. That being

said we can also realize it in an efficient way if we use just one point. We can use for this case values of polynomial, and its first and second derivative at current point.

Accordingly there are two versions of Müller's method: **MM1** and **MM2**.

### 2.2.1 MM1

Given three points:  $x_0; x_1; x_2$  and their polynomial values:  $f(x_0), f(x_1), f(x_2)$  we construct a (quadratic) function passing through these points. Then we find roots of this parabola and we choose one of these roots for the approximation of the result.

For example: Assume that  $x_2$  is the approximation of the root. Let's introduce variable  $z$  such that:

$$z = x - x_2$$

And differences:

$$z_0 = x_0 - x_2$$

$$z_1 = x_1 - x_2$$

We have quadratic function:

$$y(z) = az^2 + bz + c$$

Using three points from above we get:

$$y(z_0) = az_0^2 + bz_0 + c = f(x_0)$$

$$y(z_1) = az_1^2 + bz_1 + c = f(x_1)$$

$$y(z_2) = c = f(x_2)$$

And then we get system of equation that we can solve to find  $a$  and  $b$ :

$$az_0^2 + bz_0 = f(x_0) - f(x_2)$$

$$az_1^2 + bz_1 = f(x_1) - f(x_2)$$

Roots are equal to:

$$z_+ = \frac{-2c}{b + \sqrt{b^2 - 4ac}}$$

$$z_- = \frac{-2c}{b - \sqrt{b^2 - 4ac}}$$

We choose a root with smaller absolute value for next iteration:

$$z_{min} = \min |z_+, z_-|$$

$$x_3 = x_2 + z_{min}$$

Then we choose new point  $x_3$  and two selected from  $x_0, x_1, x_2$  which were closer to  $x_3$ .

This method should also work for  $\Delta < 0$

### 2.2.2 MM2

This method being numerically more effective is usually recommended. We calculate values of a polynomial and its first and second derivatives at one point.

from definition of quadratic function:

$$y(z) = az^2 + bz + c$$

we can get:

$$z = x - x_k$$

If  $z = 0$  then:

$$y(0) = c = f(x_k)$$

$$y'(0) = b = f'(x_k)$$

$$y''(0) = 2a = f''(x_k)$$

We can derive from that formula for roots:

$$z_{\pm} = \frac{-2f(x_k)}{f'(x_k) \pm \sqrt{(f'(x_k))^2 - 2f(x_k)f''(x_k)}}$$

Then we choose root with smaller absolute value for next iteration:

$$x_{k+1} = x_k + z_{min}$$

Again this method should be implemented in complex number arithmetic. This method is locally convergent with order of convergence equal to 1.84. It is locally more effective than secant method and it is almost as fast as Newton's method while being capable of finding complex roots. It can be used to find roots of polynomials or another nonlinear functions.

6	0.17188+0.56551i	0

### 2.3.5 Comparison of results between MM1 and MM2

As we can see MM2 method is much better, it took on average around 5 iterations for it to find a root with sufficient accuracy compared to around 7 iterations that MM1 needed to find roots. MM1 is slightly more accurate with at least 10 times better accuracy than MM2, there is also a big error in MM2 result which incorrectly denotes a number that should only have real part as an imaginary number. MM1 does not have this problem and shows root -0.67787 correctly. We can also observe that MM1 calculated complex root with a '-' between real and imaginary part and MM2 calculated complex root with a '+' between real and imaginary part. We can assume that in order to get all the complex roots we should use both of the methods.

We can also observe that on graphs with MM2 approaching the root faster than MM1 and MM1 being slightly more accurate.

### 2.3.6 Comparison of results between Newton's method and MM2

Iteration	root	f(root)
1	-1.25	1.8879
2	-0.92681	-5.52
3	-0.74804	-1.159
4	-0.68543	-0.11186
5	-0.67797	-0.0014548
6	-0.67787	-2.568e-07
7	-0.67787	-7.9936e-15

Iteration	root	f(root)
1	6.25	-0.23707
2	6.3376	-1.8647
3	6.3341	-0.0029912
4	6.3341	-7.7134e-09
5	6.3341	-7.1942e-14

As we can see Newton method calculated real roots in around the same number of iterations as method MM1, it was slightly slower than MM2. Newton method had pretty good accuracy, comparable to MM1 accuracy.

## Chapter 3

# Find real and complex roots of the polynomial using Laguerre's method

### 3.1 Problem

We have to find all (real and complex) roots of the polynomial from previous exercise:

$$f(x) = -2x^4 + 12x^3 + 4x^2 + 1x + 3$$

Using the Laguerre's method. Then we should compare those results with the MM2 version of the Müller's method.

### 3.2 Theoretical Introduction

Laguerre's method is defined by a single formula:

$$x_{k+1} = x_k - \frac{nf(x_k)}{f'(x_k) \pm \sqrt{(n-1)[(n-1)((f'(x_k))^2 - nf(x_k)f''(x_k))]}}$$

Where:  $n$  - order of the polynomial

This formula is similar to the one from MM2 but also takes order of the polynomial into consideration. In general this method is better. For polynomials with real roots it is globally convergent. It does not have formal

analysis for complex roots but it usually shows good numerical properties, although divergence may happen.

### 3.3 Results

Iteration	root	f(root)
1	-1.25	-20.32
2	-0.67905	-0.017268
3	-0.67787	-3.1489e-07

6	0.17188+0.56551i	0

### 3.3.1 Comparison of results between Laguerre's method and MM2 method

Tables for MM2

Iteration	root	f(root)
1	-1.25+0i	-20.32+0i
2	-0.72604-0.25326i	1.0515-4.0744i
3	-0.68613-0.01483i	-0.11667-0.22303i
4	-0.67788+2.5407e-06i	-0.00010163+3.7123e-05i
5	-0.67787-8.0819e-13i	1.4105e-11-1.1809e-11i

Iteration	root	f(root)
1	6.25	43.43
2	6.3376	-1.8647
3	6.3341	0.0029695
4	6.3341	1.6294e-08
5	6.3341	-4.6896e-13

Iteration	root	f(root)
1	0+0i	3
2	-0.125+0.85696i	8.0341
3	0.16892+0.62593i	0.94053
4	0.17203+0.56536i	0.0031354
5	0.17188+0.56551i	3.8615e-09
6	0.17188+0.56551i	0

As expected Laguerre's method reigns supreme, it is:

1. Faster With 5 iterations on average compared to around 5.3 for MM2

2. More accurate For real root -0.67787 matlab calculated the value of this function for Laguerre's method as equal to exactly 0 as opposed to around  $10^{-11}$  error for MM2.
3. With no errors Laguerre's method did not mistakenly added imaginary part to real root -0.67787 as MM2 did.

Laguerre's method is faster and more accurate than MM2 which means that we can compare it to faster version of MM1, this means that it is the best method we tested in this exercise.
